Evaluation of a Computer-aided Lung Auscultation System for Diagnosis of Bovine Respiratory Disease in Feedlot Cattle

A.V. Mang, S. Buczinski, C.W. Booker, and E. Timsit

Background: A computer-aided lung auscultation (CALA) system was recently developed to diagnose bovine respiratory disease (BRD) in feedlot cattle.

Objectives: To determine, in a case–control study, the level of agreement between CALA and veterinary lung auscultation and to evaluate the sensitivity (Se) and specificity (Sp) of CALA to diagnose BRD in feedlot cattle.

Animals: A total of 561 Angus cross-steers (initial body weight = 246 ± 45 kg) were observed during the first 50 day after entry to a feedlot.

Methods: Case-control study. Steers with visual signs of BRD identified by pen checkers were examined by a veterinarian, including lung auscultation using a conventional stethoscope and CALA that produced a lung score from 1 (normal) to 5 (chronic). For each steer examined for BRD, 1 apparently healthy steer was selected as control and similarly examined. Agreement between CALA and veterinary auscultation was assessed by kappa statistic. CALA’s Se and Sp were estimated using Bayesian latent class analysis.

Results: Of the 561 steers, 35 were identified with visual signs of BRD and 35 were selected as controls. Comparison of veterinary auscultation and CALA (using a CALA score ≥ 2 as a cut off) revealed a substantial agreement (kappa = 0.77). Using latent class analysis, CALA had a relatively high Se (92.9%; 95% credible interval [CI] = 0.71–0.99) and Sp (89.6%; 95% CI = 0.64–0.99) for diagnosing BRD compared with pen checking.

Conclusions: CALA had good diagnostic accuracy (albeit with a relatively wide CI). Its use in feedlots could increase the proportion of cattle accurately diagnosed with BRD.

Key words: Bayesian latent class analysis; Electronic stethoscope; Whisper®.

Accurate diagnosis of bovine respiratory disease (BRD) in feedlot cattle is crucial for effective treatment and implementation of prevention strategies. Furthermore, because BRD treatment relies mainly on use of antimicrobials, an accurate BRD diagnosis should promote prudent use of antimicrobials by reducing unnecessary treatments. Unfortunately, current diagnostic methods to identify feedlot cattle affected with BRD are not always accurate. Indeed, these methods, based on visual inspection by pen checkers, are highly subjective, even when combined with measurement of rectal temperature. Based on a latent class analysis using clinical inspection throughout the feeding period and presence of lung lesions at slaughter as tests for BRD diagnosis, the sensitivity (Se) and specificity (Sp) of clinical inspection were 62 and 63%, respectively.

Several methods including lung ultrasonography, radiographs, lung auscultation, determination of serum haptoglobin concentration have been used to improve accuracy of BRD diagnosis. Among these methods, lung auscultation is inexpensive, can be conducted chute side and is highly specific in dairy calves compared with ultrasonographic assessment of lung lesions. Unfortunately, lung auscultation is also subjective and requires a well-trained person with good acoustic abilities to correctly recognize abnormal sounds. To overcome these drawbacks, a computer-aided lung auscultation (CALA) system has been developed. By automatically classifying acoustic patterns in lung scores, this system could increase accuracy of BRD diagnosis. However, to be useful its accuracy to diagnose BRD must be critically evaluated in a case–control study.

The objectives were to: (1) determine the level of agreement between CALA and lung auscultation by an experienced veterinarian and; (2) evaluate using Bayesian latent class analysis the diagnostic accuracy (Se, Sp) of CALA for BRD in feedlot cattle. We
hypothesized that a moderate to substantial agreement exists between CALA and veterinary auscultation and that CALA is an accurate method to diagnose BRD.

Materials and Methods

Animals

All management and procedures were reviewed and approved by the University of Calgary Animal Care Committee (AC13-0212) and were in accordance with guidelines of the Canadian Council on Animal Care.7

Angus cross-steers (n = 561; initial body weight = 246 ± 45 kg) at high risk of developing BRD because of recent weaning, commingling and being auction-market derived were studied during the first 50 day after their arrival at a commercial feedlot in Western Canada. Upon arrival, steers were allowed to rest for at least 12 h (with ad libitum access to hay and water) before processing. At processing, steers received a subcutaneous injection of a long-acting macrolideb and were vaccinated against infectious bovine herpes virus-1,1 bovine viral diarrhea virus (types I and II),c bovine parainfluenza-3,d bovine respiratory syncytial virus,e Mannheimia haemolytica,d Histophilus somni,e and clostridial pathogens. Steers were also dewormed with pour-on ivermectin solution.f

Steers were fed in 2 large outdoor dirt-floor pens (67 × 61 m with a 64-m fence-line concrete feed bunk) with approximately 280 steers per pen. Steers were fed twice daily, at 0630 and 1430 hours, a 55% concentrate receiving/growing diet formula (≥ 0.41 concentrate, 0.20 protein, 0.21 fat, 0.61–0.80 fiber). g The first 50 day after their arrival at a commercial feedlot in Wes-}

Study Design: Case–Control Study

During the study period, steers were observed daily by experienced pen checkers for detection of clinical illness. Steers with visual signs of BRD including one or more of depression, nasal or ocular discharge, cough, increased respiratory rate, and labored breathing were removed from the pen by pen checkers and examined by an experienced veterinarian. For each steer suspected of having BRD, 1 apparently healthy steer with no visual signs of BRD or other disease was conveniently selected based on proximity to the gate or apparently sick animal as pen-matched control and similarly examined. Clinical examination included measurement of respiratory rate using a stopwatch and rectal temperature, complete lung auscultation using a conven-}

Serum Haptoglobin Determination

In addition to clinical examination, a blood sample was collected from each steer to detect inflammation by measurement of serum haptoglobin (Hap) concentration. Serum haptoglobin concentra-

Data Analysis

Clinical findings (rectal temperature, respiratory rate per minute, serum Hap concentrations) between cattle examined for BRD and cattle selected as controls by pen checker were compared using nonparametric (Mann–Whitney U-test) and parametric tests (Student’s t-test).1

The level of agreement between lung auscultation by an experienced veterinarian and CALA (using a CALA score ≥ 2 as a cut off) was compared using Kappa statistic. The strength of agree-
Convergence of the model was assessed by visual inspection of the time series plots of selected variables and Gelman–Rubin diagnostic plots (after running multiple chains with various starting values). The caudal distributions of tests sensitivities and specificities and disease prevalence were reported as medians and corresponding 95% CI.

Results

Of the 561 steers, 35 (6.2%) were detected with visual BRD signs and 35 were selected as pen-matched controls. All steers with visual signs of BRD had abnormal lung sounds including one or more of increased bronchial sounds, crackles, and wheezes detected by auscultation by a veterinarian. Interestingly, 9 steers selected as controls had also abnormal lung sounds. Rectal temperatures, respiratory rates per minute, and serum Hap concentrations differed \((P < .05)\) between steers detected with visual signs of BRD and those selected as controls (Table 2).

A CALA score was obtained from all examined steers \((n = 70)\), with scores ranging from 1 to 5 (Fig. 1). Comparison of CALA results with auscultation by a veterinarian (using a CALA score \(\geq 2\) as a cut off) revealed a substantial agreement (kappa = 0.77; 95% CI, 0.62–0.92), with 62 concordant results out of the 70 clinical examinations (Table 3). The 8 discordant results were attributed to the presence of abnormal lung sounds detected by auscultation by a veterinarian, but not by CALA.

Pen checker classifications and CALA results were crossed classified into a 2 x 2 table (Table 4), which was used for the Bayesian latent class analysis. Caudal estimates (median and 95% CI) for SeCALA, SpCALA, Sepp, Sppp, and prevalence of BRD are shown (Table 1).

Indeed, moderate sensitivity is a common drawback of computerized lung sounds analysis. In a meta-analysis, algorithms for classification of lung sounds had an overall Se of 80% (95% CI = 72–86%) for detection of abnormal lung sounds (wheezes and crackles) in humans when compared with auscultation by a trained person. However, further research is needed to confirm this hypothesis, as Se of auscultation by a veterinarian was not calculated in this study.

In the absence of a perfect reference test (gold standard), the use of latent class analysis is considered to be the best method to estimate the accuracy of a new diagnostic test. Indeed, latent class analysis refers to the idea that true disease status of animals is unknown and needs to be estimated from the data. If classification errors in the reference test are ignored, serious bias can be introduced in assessment of the accuracy of the new test. For example, in a case of a reference test with a Se <100% (as pen checking, which has a Se estimated at 62.0%), samples which are falsely classified as negative by this imperfect test could be correctly detected as positive by a more sensitive new test, thus leading to a biased estimate of Sp (in this case, too low) of the new test.

Furthermore, the Bayesian model used in this study allowed for incorporation of prior scientific information on variables to estimate (test accuracies and disease prevalence). However, because we had a relatively small sample size, we chose noninformative prior probability distributions for SeCALA and SpCALA. Although the use of noninformative prior distributions allows caudal densities to be impacted more by the data than by the prior distributions, this could also explain why the 95% CI for SeCALA and SpCALA were relatively wide. Further research is therefore needed to narrow these.

Computer-aided lung auscultation had good diagnostic accuracy with relatively wide CI with SeCALA and SpCALA estimated at, respectively, 92.9% (95% CI, 0.71–0.99) and 89.6% (95% CI, 0.64–0.99). Compared with CALA, pen checker’s accuracy was lower with SeP and SpP, estimated at, respectively, 63.5% (95% CI, 0.58–0.69) and 63.5% (95% CI, 0.60–0.66).

### Discussion

In this study, there was a substantial level of agreement between CALA and lung auscultation performed by an experienced veterinarian. Compared with pen checking using Bayesian latent class analysis, CALA also had a relatively high Se (92.9%; 95% CI = 0.71–0.99) and Sp (89.6%; 95% CI = 0.64–0.99) for diagnosing BRD in feedlot cattle.

The substantial agreement between CALA and veterinary auscultation was expected as CALA’s algorithm was initially trained to correctly classify abnormal lung sounds detected by experienced veterinarians (R. Geissler, personal communication). In this study, veterinary auscultation nevertheless detected abnormal lung sounds more often than CALA. This finding could be explained by a higher sensitivity of veterinary auscultation. Indeed, moderate sensitivity is a common drawback of computerized lung sounds analysis. In a meta-analysis, algorithms for classification of lung sounds had an overall Se of 80% (95% CI = 72–86%) for detection of abnormal lung sounds (wheezes and crackles) in humans when compared with auscultation by a trained person. However, further research is needed to confirm this hypothesis, as Se of auscultation by a veterinarian was not calculated in this study.

In the absence of a perfect reference test (gold standard), the use of latent class analysis is considered to be the best method to estimate the accuracy of a new diagnostic test. Indeed, latent class analysis refers to the idea that true disease status of animals is unknown and needs to be estimated from the data. If classification errors in the reference test are ignored, serious bias can be introduced in assessment of the accuracy of the new test. For example, in a case of a reference test with a Se <100% (as pen checking, which has a Se estimated at 62.0%), samples which are falsely classified as negative by this imperfect test could be correctly detected as positive by a more sensitive new test, thus leading to a biased estimate of Sp (in this case, too low) of the new test.

Furthermore, the Bayesian model used in this study allowed for incorporation of prior scientific information on variables to estimate (test accuracies and disease prevalence). However, because we had a relatively small sample size, we chose noninformative prior probability distributions for SeCALA and SpCALA. Although the use of noninformative prior distributions allows caudal densities to be impacted more by the data than by the prior distributions, this could also explain why the 95% CI for SeCALA and SpCALA were relatively wide. Further research is therefore needed to narrow these.

It is noteworthy that the prior probability distributions chosen for pen checkers’ Se and Sp were based on a previous study and thus might not represent the Sp of the pen checkers involved in this study, which could influence the accuracy of CALA. However, additional analyses were conducted using modified prior distributions and similar results for the CALA’s Se and Sp were obtained. Indeed, by using a pen checker’s Se and Sp ranging from 50 to 100% with a best guess of 75% (beta distribution: 9.63–3.88), it was estimated that a CALA’s Se and Sp of 91.9% (95% CI, 74.0–99.6) and 90.3% (95% CI, 71.1–99.5), respectively (data not show). Therefore, the authors are confident that the choice of prior probability distributions based on a previous study did not bias the findings of this study.

The sensitivity obtained in this study for CALA was higher than anticipated. In a previous study of dairy calves, Se of lung auscultation to diagnose BRD (defined as lung consolidation detected with ultrasonography) was only 5.9% (range, 0–16.7%). This difference in Se can be explained by the fact that CALA’s algorithm included increased bronchial breath sounds for calculation of lung scores, whereas in this previous study, only crackles, wheezes or absence of respiratory

* Cattle with a CALA score ≥2 were considered BRD positive (+), whereas cattle with a CALA score = 1 were considered BRD negative (–).
Computer-aided Lung Auscultation

Sounds was interpreted as abnormal. Indeed, in this previous study, investigators did not interpret bronchial breath sounds (although highly Se to diagnose BRD) as these sounds were considered too subjective. The main advantage of CALA resides in its algorithm that can provide an objective lung score and thereby minimize bias.

On the basis of the higher specificity of CALA compared with pen checker, we inferred that this technology has the potential to decrease the proportion of cattle falsely diagnosed with BRD and thus, could promote prudent use of antimicrobials in commercial feedlots by reducing unnecessary treatments. Interpretation of CALA results in cattle previously identified by pen checkers as BRD-affected which is serial interpretation scheme with conditional independence, could increase the overall Sp of BRD diagnosis in feedlot cattle (Sp<sub>CALA</sub> = Sp<sub>p</sub> + Sp<sub>CALA</sub> − (Sp<sub>p</sub> × Sp<sub>CALA</sub>) = 96.1%) compared with pen checking alone (Sp<sub>p</sub> = 63.0%). Furthermore, CALA does not require experience in lung auscultation and therefore could be easily used by the feedlot employees who have primary responsibility for diagnosis and treatment of BRD.

In conclusion, this study showed that CALA was a promising technology to improve accuracy of BRD diagnosis in feedlots. Its use could increase the proportion of cattle accurately diagnosed with BRD by a reduction in false-positive diagnoses.
